Consider a dataset $D=(\pmb{x_i},\pmb{y_i})^N$ of N data points, where $\pmb{x_i}=(\pmb{x_{i1}},\pmb{x_{i2}},\cdots,\pmb{x_{iM}})$ is a feature vector with M features, and $\pmb{y_i}$ is the target, i.e., the response, variable. Let $\pmb{x_j}$ denote the jth variable in feature space. A typical linear regression

$$y = oldsymbol{eta_0} + oldsymbol{eta_{1}} x_1 + oldsymbol{eta_{2}} x_2 + \cdots + oldsymbol{eta_{M}} x_M$$

model can then be expressed mathematically as:

prediction vector

This model assumes that the relationships between the target variable y_i and features x_j are linear and can be captured in slope terms $\beta_1, \beta_2, \ldots, \beta_M$.
